## ABSTRACT

We present deep ( $>2.4$  Ms) observations of the Cassiopeia A supernova remnant with *NuSTAR*, which operates in the 3–79 keV bandpass and is the first instrument capable of spatially resolving the remnant above 15 keV. We find that the emission is not entirely dominated by the forward shock nor by a smooth “bright ring” at the reverse shock. Instead we find that the  $>15$  keV emission is dominated by knots near the center of the remnant and dimmer filaments near the remnant’s outer rim. These regions are fit with unbroken power laws in the 15–50 keV bandpass, though the central knots have a steeper ( $\Gamma \sim -3.35$ ) spectrum than the outer filaments ( $\Gamma \sim -3.06$ ). We argue this difference implies that the central knots are located in the 3-D interior of the remnant rather than at the outer rim of the remnant and seen in the center due to projection effects. The morphology of  $>15$  keV emission does not follow that of the radio emission nor that of the low energy ( $<12$  keV) X-rays, leaving the origin of the  $>15$  keV emission an open mystery. Even at the forward shock front we find less steepening of the spectrum than expected from an exponentially cut off electron distribution with a single cutoff energy. Finally, we find that the GeV emission is not associated with the bright features in the *NuSTAR* band while the TeV emission may be, suggesting that both hadronic and leptonic emission mechanisms may be at work.

**Key words:** acceleration of particles – ISM: individual objects (Cassiopeia A) – ISM: supernova remnants – radiation mechanisms: non-thermal – X-rays: ISM

## 1. INTRODUCTION

Young supernova remnants (SNRs) such as Cassiopeia A (Cas A) with shock velocities above  $1000 \text{ km s}^{-1}$  provide excellent opportunities to study in detail the process of shock acceleration of electrons to high energies (see Reynolds 2008 for a review). As the youngest Galactic remnant of a core-collapse (CC) supernova with an estimated explosion date of 1670 (Thorstensen et al. 2001), Cas A is particularly important for contrasting with the historical remnants of Type Ia events, such as Tycho, *Kepler*, SN 1006, and G1.9+0.3 (although the identification as a Type Ia is less secure for G1.9+0.3). Non-thermal X-ray emission from all these objects can be characterized both spectrally and spatially and can be used to infer properties of the acceleration process. Of special interest for shock acceleration physics is the maximum energy to which electrons are accelerated,  $E_m$ , and its dependence on the local shock velocity and other parameters. For example, the “thin rims” of synchrotron X-rays found at the peripheries of some SNRs imply strong magnetic-field amplification (Vink & Laming 2003; Parizot et al. 2006; Ressler et al. 2014) which, along with spectral inferences, gives an assumed exponential cutoff in the electron spectrum with  $e$ -folding energies in the range 10–100 TeV.

Cas A has now been shown by light echoes to be the result of a SN IIb explosion where the progenitor lost most of a massive H envelope prior to the explosion (Krause et al. 2008). This implies that the remnant is currently expanding into the progenitor’s stellar wind and so the blast wave should be quasi-perpendicular over most of its surface. Since the properties of shock acceleration are strongly dependent on the magnetic obliquity angle  $\theta_{Bn}$  between the shock velocity and the upstream magnetic field, one expects substantial differences in both the morphology and spectrum of synchrotron emission between remnants of CC and Type Ia events. In particular, many models (e.g., Riquelme & Spitkovsky 2010) assert that acceleration at quasi-perpendicular shocks ( $\theta_{Bn} \sim 90^\circ$ ) is considerably different from that at quasi-parallel shocks, so that remnants expanding into stellar winds might have very different properties in their non-thermal emission.

The spectral properties and basic morphology of Cas A in X-rays between 0.5 and 12 keV are well known from many previous studies, especially with *XMM-Newton* (Bleeker et al. 2001; Willingale et al. 2002) and *Chandra* (Gotthelf et al. 2001; Hwang et al. 2004). Thermal emission from the shocked ejecta dominates the integrated spectrum at these energies, with electron temperatures typically between 1 and

Total	≈2.4 Ms	

3 keV and in no cases above 6 keV. Local variations have been mapped out on arcsecond length scales (Hwang & Laming 2012); in almost all regions, a power-law component must be added to one or more thermal components to obtain a satisfactory description of the spectrum.

The morphology is dominated by a “bright ring” about 3/5 in diameter which is commonly associated with the reverse shock or contact discontinuity between shocked ejecta and shocked circumstellar material (CSM). Fainter emission forms a faint rim outside the bright ring (Gotthelf et al. 2001). The bright ring remains prominent to the highest energies imaged with *XMM-Newton* (Bleeker et al. 2001), with an east/west asymmetry reported in observations using *BeppoSAX* (Vink et al. 2000) and *Suzaku* (Maeda et al. 2009). These authors note that the western half of the remnant appears to be brighter in the highest energy band of both instruments. The faint rim is located at the edge of radio emission, though the outer radio emission appears to form the edge of a plateau rather than thin filaments. Many arguments suggest that the outer radio edge and the X-ray filaments are located at the outer blast wave.

The integrated spectrum of Cas A has long been known to continue above the thermal spectrum to energies of order 100 keV with a spectrum reasonably well described by a single power law, based on data from non-imaging instruments (e.g., *Compton Gamma Ray Observatory* (CGRO), The et al. 1996; *RXTE*, *HEAO-2*, and *OSSE*, Allen et al. 1997; *BeppoSAX*, Vink et al. 2000; *INTEGRAL*, Renaud et al. 2006; *Suzaku*, Maeda et al. 2009). While the tail was originally thought to be thermal, at least out to energies of 30 keV or so (Pravdo & Smith 1979), better analysis of the spectrum below 10 keV has shown that the temperature of the thermal plasmas only extends to ~3 keV (Hwang & Laming 2012). Subsequent explanations for the high-energy tail have included non-thermal bremsstrahlung from a power-law distribution of somewhat suprathermal electrons (e.g., Asvarov et al. 1990; Bleeker et al. 2001) and synchrotron emission from shock-accelerated electrons with much higher energies (e.g., Allen et al. 1997). While the hard tail can be associated with the power-law components required in the modeling of the emission below 10 keV, the temperature and flux of the thermal components vary with position in the remnant. It is not clear how much of the flux below 10 keV is associated with the non-thermal component. In relatively line-

free regions of the spectrum such as 4.2–6 keV, estimates range from a few percent to half or more (e.g., Rothschild & Lingenfelter 2003; Helder & Vink 2008).

The argument over the emission mechanism of the hard tail seems to have been settled in favor of synchrotron emission. Electrons in the 10–100 keV energy range required for bremsstrahlung should be accelerated in the forward or reverse shocks, but Coulomb interactions ought to cool the electrons efficiently not far behind those shocks, producing a dip in the spectrum below 100 keV which is not observed (Vink 2008, 2012). Electron energization by lower hybrid waves in weak shocks in the remnant’s interior might ameliorate this problem (Laming 2001). The presumptive site for the production of the very high-energy electrons required to produce synchrotron emission to 10 keV is the forward blast wave marked by the faint rim filaments (e.g., Berezhko & Völk 2004), though a recent model proposes that almost all emission above 10 keV should come from the reverse shock (Zirakashvili et al. 2014). Therefore, current theories expect the >15 keV emission to predominantly originate in either the forward shock or the bright ring.

High spatial resolution observations with *XMM* and *Chandra* show that in addition to the clear outer rim and bright ring, there are bright central knots and filaments of soft X-ray emission that are dominated by non-thermal continuum (DeLaney et al. 2004), with intensities that vary with time (Patnaude & Fesen 2009). Whether these features are actually interior to the remnant and evidence for particle acceleration at the reverse shock or knots on the forward shock face seen in projection has remained an open question. It is not known whether the bright ring of the reverse shock, the outer rim of the forward shock, or something else, dominates the emission above 15 keV, which has significant implications for the particle acceleration in the remnant.

In this paper we report on the first spatially resolved hard X-ray images and spectroscopy of Cas A. These collected observations represent over 2.4 Ms of integration time, with the exposure time primarily driven by the study of  $^{44}\text{Ti}$  in the remnant (Grefenstette et al. 2014). This results in deep observations that provide unprecedented sensitivity in the hard X-ray band. These observations allow us to make important new measurements: better spectral characterization of the hard continuum (results from previous missions are not entirely consistent with one another), spatial identification of the sites of electron acceleration to the highest energies, and detailed spectral modeling over most of the energy range of observed X-ray emission. Fully exploiting this new energy band requires extensive analysis combining spatially resolved information from the radio, soft X-rays, and hard X-rays. In this paper we present the initial results from the *NuSTAR* observations. We compare and contrast our findings with the previously known characteristics of Cas A and discuss the implications for particle acceleration models. In addition, we provide context for this work by performing a high-level comparison of our findings in the hard X-ray band with previous work in the radio and soft X-ray bands. While the broadband picture is by no means complete, we expect that this will motivate the future theoretical modeling of the Cas A continuum.

## 2. *NUSTAR* DATA AND METHODS

Cas A was observed by *NuSTAR*, a NASA Small Explorer (*SMEX*) satellite launched on 2012 June 13 (Harrison

**Figure 1.** Deconvolved *NuSTAR* images of Cas A: red (4–6 keV), green (8–10 keV) and blue (10–15 keV). For this and all the images below north is up and east is left. These images are 7.6 arcmin on a side and all of the color bands have a `sqrt` stretch. As the energy bands increase, the emission is more consistently dominated by the central knots rather than any diffuse emission in the remnant. However, even in the highest energy bands accessible to *NuSTAR* there is still some residual diffuse emission in the center of the remnant not associated with any obvious point sources. See online version for color images.

et al. 2013). *NuSTAR* has two co-aligned X-ray telescopes observing the sky in an energy range from 3–79 keV. The field of view is roughly  $12' \times 12'$ , with a point-spread function (PSF) with an FWHM of  $18''$  and a half-power diameter of  $58''$ .

The observations were completed over the first 18 months of the mission (Table 1) with exposures spanning between 120 and 280 ks in a single pointing. The aim point for the telescope was generally selected to avoid the gaps in the instrument when possible, though later observations were chosen to target specific spatial regions for the study of  $^{44}\text{Ti}$ . Thermal motions of the 10 m mast that separates the *NuSTAR* optics and detectors as well as small variations in the spacecraft pointing introduce natural “dither” in the pointing pattern, further smoothing the exposure map. There were no roll angle constraints on these observations, so the remnant was observed at different position angles over the course of the observations.

We reduced the *NuSTAR* data with the *NuSTAR* Data Analysis Software (NuSTARDAS) version 1.3.1 and *NuSTAR* CALDB version 20131223. The NuSTARDAS pipeline software and associated CALDB files are fully HEASARC FTOOL compatible and are written and maintained jointly by the ASI Science Data Center (ASDC, Italy) and the *NuSTAR* Science Operations Center (SOC) at Caltech. The NuSTARDAS pipeline generates Good Time Intervals (GTIs) for each observation that excludes periods when the source is occulted by the Earth and when the satellite is transiting the South Atlantic Anomaly (SAA), a region of high particle background. The default detector “depth cut” is applied to reduce the internal background at high energies. The images, exposure maps, and response files produced by the NuSTARDAS consistently account for the natural thermal motions of the mast.

We produced images in various bandpasses using the XSELECT multi-mission FTOOL. Cas A is a bright, extended source so there are no regions in the field of view of the telescope that can be used to directly estimate the background in the source region. Instead we model the background and produce energy-dependent background images. We follow the procedure outlined in Grefenstette et al. (2014) and Wik et al.

(2014) to estimate the background components and their spatial distributions using the *nuskybgd* IDL suite. In general, the flux from Cas A dominates over the diffuse backgrounds by several orders of magnitude until energies of  $\sim 50$  keV where the signal becomes comparable to the background.

We combined images from all epochs using XIMAGE, taking into account the unique time-dependent exposure and vignetting corrections for each pointing. We chose the energy bands of 4–6, 8–10, 10–15, 15–20, 20–25, 25–35, 35–45, and 45–55 keV for analysis. We omit the 6–8 keV energy band from this work, as it is dominated by Fe line emission from the shocked ejecta and has been explored previously in detail (e.g., Hwang & Laming 2012). Here we are primarily interested in the continuum emission. For energy bands up to the 25–35 keV we deconvolved the images with the on-axis *NuSTAR* PSF contained in the CALDB and the `max_likelihood AstroLib` IDL script which is based on a Richardson–Lucy deconvolution for images with Poisson noise. We chose to halt the deconvolution after 50 iterations since after this the resulting images became sufficiently self-similar. For the 35–45 and 45–55 keV bands there are insufficient statistics to support the image deconvolution, so we instead smoothed the images with top-hat smoothing kernels with radii of 10 pixels ( $\sim 25''$ ).

To perform spatially resolved spectroscopy we defined standard ds9 region files and used the *nuproducts* FTOOL to extract spectra and produce ancillary response files (ARFs) and redistribution matrix files (RMFs) for each epoch with background spectra simulated using *nuskybgd*. To reduce the complexity of joint-fitting many spectra ( $14 \text{ ObsIds} \times \text{two telescopes} = 28 \text{ spectra}$ ), we combined the source pulse-height amplitude (PHA) files, ARFs, and simulated background PHA files using the *addascaspec* FTOOL and combined the RMF using the *addrmf* FTOOL. This results in exposure-weighted RMF and ARF files for each region. Based on many observations of the Crab at different off-axis angles (K. K. Madsen et al., 2015 in preparation), we estimated that the systematic effects caused by combining the spectra in this manner are energy-independent and introduce noise primarily in the normalization of the combined spectrum that is on the order of a few percent. As we are not interested here in the absolute normalization of the spectra, we ignore this effect below. We also estimate that this introduces a systematic error on the power-law index of  $\pm 0.01$ , which is significantly smaller than the statistical errors quoted below. As we are mostly interested in the non-thermal emission processes, we only fit the data from 15–50 keV. The lower energy bound was chosen to so that the contribution from thermal bremsstrahlung from the shock-heated ejecta studied in detail by *Chandra* and *XMM-Newton* is negligible, while at high energies we chose 50 keV since above this energy the signal from our source regions becomes comparable to the background and mentioned above.

### 3. RESULTS

#### 3.1. *NuSTAR* Imaging

While the spatially integrated hard X-ray emission from Cas A has been measured by a number of instruments, *NuSTAR* provides the first opportunity to spatially resolve the emission above 15 keV (Figures 1–3). We adopt the terminology of

**Figure 2.** Deconvolved *NuSTAR* images of Cas A: red (15–20 keV), green (20–25 keV), and blue (25–35 keV).

“exterior” emission features to be those seen near the outside of the remnant when seen in projection on the sky and “central” emission features to be those seen toward the center of the remnant when seen in projection on the sky. We also adopt a description of “knots” of emission as those regions that are unresolved by *NuSTAR* and “filaments” as those that appear to be linearly extended regions of emission.

We find that above 15 keV the morphology of the remnant begins to deviate from the emission below 12 keV observed by *Chandra*, *XMM-Newton*, and *Suzaku*. While the outer filaments (i.e., the “thin rim” of the forward shock) are clearly visible in the *NuSTAR* images, the emission is dominated by two central unresolved knots in the west. These western central knots dominate the hard X-ray emission above 15 keV, which is broadly consistent with the results from Helder & Vink (2008), who found a global east/west asymmetry in the hardness ratio of the remnant based on data from *Chandra*, implying that the west should be brighter at higher energies. However, we note that though the central western knots dominate the emission, the tricolor image above 15 keV (Figure 2) demonstrates that the exterior filaments are harder (bluer) than the central knots, a fact we explore quantitatively below.

### 3.2. Spatially Resolved Spectroscopy

With *NuSTAR* we can separately analyze the non-thermal continuum originating from different spatial regions of the remnant. Figure 4 shows the 8–10 keV *NuSTAR* image along with the extraction regions that we used for this work.

We find that all of the regions are well fit by unbroken power-law models across the 15–50 keV band. The exterior filaments (the regions labeled “northeast” and “southeast” in Figure 4) have similar spectra, with power-law indices of  $\Gamma \sim -3.06$ , while the interior bright knots (the “knot” regions in Figure 4) also have similar spectra, but in general have a softer power-law index of  $\Gamma \sim -3.35$ . We fit all of the regions independently but, for clarity, show the combined spectra and best-fit models for the exterior and interior regions in Figure 5 while the best-fit model parameters and  $2\sigma$  error ranges are given in Table 2.

At soft X-ray energies (<10 keV), the presence of lines associated with ionized S, Fe, and Ni (as well as lighter species below the calibrated *NuSTAR* band) indicate the presence of a hot thermal plasma. We do not attempt to model these thermal

plasmas since we know from analysis with *Chandra* that the plasma properties may vary on  $\sim$ arcsecond spatial scales (Stage et al. 2006; Hwang & Laming 2012) and the relatively large *NuSTAR* regions will sample many regions with different physical parameters. However, we note that when we extrapolate the power-law fits from the 15–50 keV band to soft X-ray energies (<10 keV) we see different behavior for the exterior filaments and the central knots; the power-law model for the exterior filaments underpredicts the observed spectrum at soft X-ray energies while the power-law model for the central knots overpredicts the observed spectrum. We discuss the implications of this below.

### 3.3. Multiwavelength Comparisons

Figure 6 shows a comparison between the radio (6 cm intensity maps obtained with the VLA), soft X-rays (4–6 keV continuum images taken with *Chandra* from Hwang et al. 2004), and the 10–15 keV hard X-ray observed by *NuSTAR*.

#### 3.3.1. Hard X-rays and Radio

The hard X-ray and radio morphologies of Cas A are substantially different (Figure 7). The outer filaments in the northeast and southeast visible in *NuSTAR* are coincident with the edge of faint radio emission in the VLA images, but the radio morphology is not of thin tangential filaments but simply is simply described by a broad plateau. Any filamentary structure could be unobserved due to a lack of dynamic range in the radio images (i.e., the radio emission from this region is faint compared to the emission in the bright ring) or to a change in the shape of the continuum extending to the radio. We do not see any enhancements in the hard X-ray images near the center of the remnant where we see the bright ring in the radio emission. Instead, we see that in the eastern half of the remnant there is little hard X-ray emission associated with the bright ring, while in the western half of the remnant the bright central knots appear to be located near the bright ring.

#### 3.3.2. Hard X-rays and Soft X-rays

We find that the *Chandra* and *NuSTAR* images (Figure 8) generally agree on large spatial scales up to  $\sim$ 10–15 keV, but show differences in the higher energy bands observed by *NuSTAR*. Up to 15 keV, the exterior filaments in the forward shock of Cas A in the north, northeast, south, and southeast seen with *Chandra* are all clearly visible in the <15 keV *NuSTAR* images, as are some of the interior emission which is likely to be residual flux from hot thermal plasmas leaking into the *NuSTAR* band. It is in the relative intensity of the central knots that we note the major differences, with the western knots dominating much of the hard X-ray flux in the 10–15 keV band in *NuSTAR* while they appear relatively unremarkable in the *Chandra* images, even when steps are taken to reduce the impact of the bright thermal emission in Cas A (e.g., using imaging tomography as per DeLaney et al. 2004). This difference becomes more apparent in the images at higher energies (Figures 2 and 3), with the central knots in the west dominating the emission above 15 keV and the bright ring completely disappearing in these energy bands. At the highest energies (Figure 3) the emission appears to be mostly attributable to several of the bright knots, with the outer rims fading away. Several of the central knots are also

**Figure 3.** *NuSTAR* images of Cas A in the 35–45 keV band (left) and 45–55 keV band (right). The images have been smoothed using a top-hat smooth kernels of 10 pixels ( $\sim 25''$ ) and both have a `sqrt` scaling. The color stretch has been modified for illustrative purposes.

**Figure 4.** Spectral extraction regions. The 15–20 keV *NuSTAR* image of Cas A shows an  $8 \times 8$  arcminute region around the remnant shown with an aggressive stretch to highlight the residual diffuse emission through the remnant. Also shown are the extraction regions used in the spectral analysis: the green circles are the representative central knot regions (all of which have similar spectra), while the red ellipses are the northeast and southeast exterior filaments. These latter regions roughly correspond to exterior filaments of Patnaude & Fesen (2009) and filaments 1, 2, 3, and 9 of Araya et al. (2010). The cyan dashed circles are the approximate locations of the forward and reverse shocks from Gotthelf et al. (2001).

near regions noted by Patnaude & Fesen (2009) and Uchiyama & Aharonian (2008) to show variability in the 4–6 keV continuum emission on timescales of a year, which we discuss below.

### 3.3.3. Radio, Soft, and Hard X-rays

Figure 9 shows the overlay of the radio, soft, and hard X-ray images. In the particular case of the western knots, we find that the two hard X-ray knots observed by *NuSTAR* differ from both the soft X-ray and radio images. Figure 10 shows a zoomed-in view around the two western knots, with the *Chandra* and the VLA observations smoothed to approximately the same spatial scales as the *NuSTAR* deconvolved images. We see that the radio is clearly strongest near the western of the two knots, *Chandra* shows some flux near the eastern knot but is still dominated by the western knot, while *NuSTAR* observes two knots of nearly equivalent brightness. These central knots are

**Figure 5.** Combined spectra of exterior filaments and central knots of Cas A. The combined spectrum from the northeast and southeast external filaments is shown in black (upper curve), while the combined spectrum of the central knots is shown in red (lower curve). The spectrum of the knots has been artificially offset downward by a factor of 10 for clarity in the top frame. The shaded region to the right is the 15–50 keV band used to fit the power-law component, which has then been extrapolated down to 3 keV. Across the 15–50 keV band the spectrum is well fit by a single power law. The normalization of the power law is allowed to vary between the different regions, though the index is tied together for the two exterior filament regions and the three central knot regions. Best-fit parameters are given in Table 2. The central knots have a softer power-law spectrum than the exterior filaments. When extrapolated to low energies, the central knots overpredict the observed emission while the exterior filaments underpredict the observed emission as demonstrated in the lower panel, which shows the ratio of the data to the models.

**Table 2**  
*NuSTAR* Power-law Fits over the 15–50 keV Band

Region	Photon Index ( $2\sigma$ Error Range)
Central Knots	$-3.35$ (3.29–3.41)
Outer Filaments	$-3.06$ (2.98–3.13)

spatially consistent with two bright knots in high-resolution maps of the radio luminosity and radio spectral index (Anderson & Rudnick 1996; DeLaney et al. 2014), with the brighter of the

**Figure 6.** *NuSTAR* continuum image of Cas A. The 10–15 keV *NuSTAR* shows the image after it has been deconvolved with the PSF. The image has been aggressively stretched to highlight the dimmer, diffuse emission from the remnant.

**Figure 7.** Comparison of the VLA 6 cm radio and *NuSTAR* continuum images of Cas A. Left: VLA 6 cm image. Right: the overlay of the VLA image with *NuSTAR* image from Figure 6.

**Figure 8.** Comparison of the *Chandra* and *NuSTAR* continuum images of Cas A. Left: *Chandra* 4–6 keV image. Right: the overlay of the *Chandra* image with *NuSTAR* image from Figure 6. The images have been stretched to highlight the dimmer, diffuse emission from both satellites.

two knots associated with a region of steeper radio spectral index while the other is associated with a region of flatter radio spectral index. The fact that *NuSTAR* sees comparably bright X-ray emission in both of these regions is puzzling.

### 3.3.4. keV, GeV, and TeV Emission

There has been improved work over the last few years localizing and studying the GeV to TeV emission from Cas A.

This is important for understanding the acceleration of cosmic rays up to the “knee” of the cosmic ray spectrum. MAGIC (Albert et al. 2007) and VERITAS (Acciari et al. 2010) have observed TeV emission that peaks in the western half of the remnant, while Yuan et al. (2013) show that the *Fermi* GeV emission peaks more toward the center of the remnant. We compare and contrast the centroids of the TeV and GeV emission with features in the 15–20 keV band (Figure 11). At the 90% level the GeV and TeV centroids are consistent with

**Figure 9.** Comparison of the *Chandra*, VLA, and *NuSTAR* continuum images of Cas A. Red: *Chandra* 4–6 keV data from the left panel of Figure 8; green: VLA 6 cm data from the left panel of Figure 7; blue: *NuSTAR* 10–15 keV data from Figure 6.

each other and could be associated with any part of the remnant. However, if we speculatively use the stricter  $1\sigma$  error limits then we note that the GeV centroid is located closer to regions of the remnant known to be bright in the infrared while the TeV centroid is closer to a bright region in the *NuSTAR* band.

We reproduce the data represented in Figure 11 as they are often reported in different coordinate systems and are shown with different confidence contours. We adopt decimal degrees in  $(\alpha, \delta)$  as our coordinate system and show  $1\sigma$  statistical errors added in quadrature with the systematic errors quoted in the literature. Albert et al. (2007) find the TeV emission centered at  $(350.79, 58.81)$ , with asymmetric errors in the  $\alpha$  direction of  $(0.003_{\text{stat}} + 0.001_{\text{sys}})$  hr, which, when added in quadrature and projected into the tangent plane at a declination of  $58^\circ 81'$ , corresponds to an error estimate of  $0^\circ 0245$ . The  $\delta$  error is  $(0^\circ 03_{\text{stat}} + 0^\circ 01_{\text{sys}})$ , or  $0^\circ 036$ , when added in quadrature. For VERITAS, the centroid shown in Acciari et al. (2010) is  $(350.825, 58.8025)$  with symmetric errors in the tangent plane of  $0^\circ 01_{\text{stat}} + 0^\circ 02_{\text{sys}}$ , or  $0^\circ 022$  when added in quadrature. The *Fermi* centroids reported in the literature vary slightly in the literature owing (we assume) to a difference in the data volume used by two authors (Yuan et al. 2013; Saha et al. 2014). The two reductions appear to largely be consistent with one another: Yuan et al. (2013) give the location in Galactic coordinates of  $(111.74, -2.12)$  corresponding to  $(\alpha, \delta)$  of  $(350.2876, 58.5513)$ , while Saha et al. (2014)

shift the centroid slightly to the northwest at coordinates  $(350.87, 58.83)$ . In both cases the errors are symmetric  $(0.01_{\text{stat}} + 0.005_{\text{sys}})$ , or  $0^\circ 0112$ .

## 4. DISCUSSION

### 4.1. Hard X-ray Morphology

Previous observations of the non-thermal continuum emission in the *Chandra* and *XMM-Newton* X-ray bands suggest a non-thermal thin rim associated with the “forward shock” (Gotthelf et al. 2001) with some additional filamentary structures through the center of the remnant (Hughes et al. 2000). Based on *XMM-Newton* data, Bleeker et al. (2001) conclude that the non-thermal emission traces the softer thermal component and that the emission does not originate from a few localized regions. We have shown for the first time that the  $>15$  keV flux from Cas A is dominated by neither the forward shock nor the bright ring (presumably the reverse shock). Instead, we find that, contrary to all expectations, the  $>15$  keV emission is dominated by the emission from several bright knots near the center of the remnant.

The nature of the central emission in Cas A has been a long-standing debate (e.g., see Helder & Vink 2008; Uchiyama & Aharonian 2008). If the central knots of emission were actually simply the exterior filaments from the outer rim of the remnant projected onto the center then we would expect the spectral shape of the central knots to be similar to the spectral shape of the exterior filaments. Our observations have conclusively shown that the spectra from the two regions are quantitatively different. This points to some systematic shift between the exterior and central spatial regions, be it a difference in the underlying electron population, a difference in how the electrons are being accelerated, a difference in how the electrons are producing X-rays, or all of these.

If the central (western) knots are located at the forward shock front then the difference in the power-law index between the different spatial regions must be attributable to some change in the physical environment (e.g., higher magnetic fields, different compression ratios in the shock front, etc). While we cannot explicitly rule out this possibility, we find it suggestive that the individual outer filaments share a similar spectrum while the individual central knots share a (different) similar spectrum. If all of the emission were coming from the forward blast wave then there would need to be some large scale physical differences between the outer rim emission seen in the northeast and southeast and the central emission seen in the west. Morphologically the central knots also appear pointlike, which is not what we would expect if we were

**Figure 10.** Comparison of the *Chandra*, VLA, and *NuSTAR* images of Cas A, zoomed in on the bright western knots. The color scheme is the same as for Figure 9. Here the *Chandra* and VLA data have been smoothed to approximately the same resolution as the *NuSTAR* 10–15 keV data and all of the images have been stretched for ease of comparison.

**Figure 11.** Comparison of the *NuSTAR* 15–20 keV  $8 \times 8$  arcmin image with the centroid locations from two *Fermi* reductions (green circle: Yuan et al. 2013; cyan circle: Saha et al. 2014), VERITAS (yellow circle: Acciari et al. 2010), and MAGIC (red ellipse: Albert et al. 2007). Note that this image is rotated with respect to the comparison of the VHE centroids to the radio image shown by Yuan et al. (2013) as those authors present the data in Galactic coordinates. All the GeV and TeV regions have a radius that corresponds to the  $1\sigma$  statistical errors added in quadrature with the systematic errors. See text for details.

seeing a face-on version of the filamentary structures on the (eastern) outer edge of the remnant. Finally, it seems unlikely that a viewing-angle dependence for the emission mechanism would conspire to alter the observed spectral index for the outer rims as compared to the central knots. We thus conclude that we are observing two relatively independent electron populations and therefore argue that the central knots are, in fact, located in the interior of the remnant.

This leaves the unsolved problem of the origin of the electrons responsible for this emission in the interior of the remnant. Helder & Vink (2008) argue, with some assumptions about the turbulence of the magnetic field, that electrons accelerated at the forward shock could not have advected to the interior of the remnant over timescales consistent with the age of the remnant and before the electrons would cool via synchrotron losses. A related observational fact is that both the emission near the exterior filaments and internal knots have been shown to vary on  $\sim$ yearly timescales (Patnaude & Fesen 2006; Uchiyama & Aharonian 2008). It is not yet clear whether these variations are caused by changes in the environment surrounding a (relatively static) population of electrons or whether some unknown mechanism is accelerating electrons in the interior of the remnant. If the latter were true, then we may also need to revisit non-thermal bremsstrahlung as a possible emission mechanism at least for the interior emission. Zirakashvili et al. (2014) has put forward the idea that the secondary electrons from the radioactive decay of  $^{44}\text{Ti}$  may be important for seeding the relativistic electron population responsible for the non-thermal X-ray emission, but as the morphology observed by *NuSTAR* is dramatically different than the morphology of the  $^{44}\text{Ti}$  in Cas A (Grefenstette et al. 2014) we do not think that this scenario is likely. We also note that if the electrons are being accelerated in the interior of the remnant at the reverse shock, we do not understand why they are only being accelerated at particular locations near the reverse shock. Again, perhaps this is driven by variation in the nature of the ejecta or the gas in the interior

of the remnant near the reverse shock. As of now, we do not see a definitive solution for this problem and leave the origin of this emission as an open mystery.

#### 4.2. The Nature of the Non-thermal Emission

The morphology of the  $>15$  keV emission is puzzling and does not appear to lend itself to a simple interpretation. Models which only produce accelerated electrons near a uniform forward shock (e.g., that only predict non-thermal emission in a thin rim surrounding the SNR) are disfavored without any of the complications due to the presence of the thermal flux in the 4–6 keV band from the shocked ejecta. The non-thermal emission (both in the radio as well as in the soft and hard X-ray bands) implies that the electrons producing the  $>15$  keV emission should be the high energy tail of the same electrons producing the radio emission. Therefore the hard X-ray morphology should follow some of the large-scale features of the radio map. We find this not to be the case and do not have a plausible explanation for why the non-thermal X-ray and radio maps differ significantly. A detailed, spatially resolved comparison of the radio spectral index and flux with the hard X-rays is required, but is beyond the scope of our present work.

It is still possible that the emission process for the bright knots is not synchrotron emission from 10–100 TeV electrons at all, but rather bremsstrahlung from electrons with only somewhat suprathermal energies of 10–100 keV. Laming (2001) suggested that lower hybrid waves at low Mach-number reflected shocks in the interior could produce such electrons. While the primary objection to such models (e.g., Vink 2008), that the electrons above thermal energies would rapidly cool due to Coulomb losses, would still need to be met, the localization of the emission into two bright knots may indicate some unique conditions that hold in the knots but not in the rest of the remnant. The predicted spectral shape of such emission can be adjusted somewhat by varying the electron Alfvén velocity, but the particular calculations of Laming (2001) all give a cutoff above  $\sim 100$  keV. If the continuum reported by *BeppoSAX* out to 300 keV were confirmed then this could disfavor this picture.

The particular case of the bright western knots may be a connection between the X-rays and the radio bands. DeLaney et al. (2005) previously noted that there are small, bright features that are found in both the arcsecond-resolution radio and soft X-ray data. One of these two knots is brighter and has a steeper radio spectrum while the other is fainter with a flatter radio spectrum. The fact that *NuSTAR* sees comparably bright X-rays from both of these knots may suggest that there may be some unknown localized physical process acting on small scales to produce the enhanced radio emission as well as the enhanced hard X-ray emission. However, the data that we are comparing are not contemporaneous and Cas A is known to vary in both the radio (Rudnick et al. 1996) and in the soft X-rays (Patnaude & Fesen 2006; Uchiyama & Aharonian 2008). We note that there now exists Jansky VLA radio images (DeLaney et al. 2014) that are contemporaneous with these *NuSTAR* observations and that these knots have not significantly changed their brightness or morphology when compared to the older VLA image. It may be the case that the bright features in the Cas A hard X-ray images are also evolving on timescales of a few years, though this is unlikely to explain the large-scale discrepancies between the radio and the hard X-ray images.

While the  $>15$  keV emission is clearly dominated by several central knots and the outer filaments, there is also diffuse emission that appears to permeate the remnant. While the central knots may be localized regions of enhanced magnetic field, density variations, or particle acceleration, the source of the diffuse central emission at energies  $>15$  keV is unclear. It is possible that this is in fact tenuous diffuse emission from the forward shock of the SNR seen in projection, or that there is a population of unresolved and relatively dim knots in the interior of the remnant. One additional possibility is that some electrons that happen to be in regions of lower mean magnetic field strength and thus are longer lived. Electrons radiating at  $\approx 15$  keV in a magnetic field of  $20 \mu\text{G}$  or less could survive for more than the 330 yr lifetime of the remnant and so could be responsible for this emission.

The hard X-ray morphology may also have implications for the interpretation of the TeV and GeV emission. The centroids of the TeV emission may be spatially consistent with the bright western knots of synchrotron emission observed by *NuSTAR*, while the *Fermi* GeV centroid has no obvious counterpart in the *NuSTAR* band. This might be expected if the TeV emission is leptonic in nature (i.e., inverse Compton scattering of cosmic microwave background photons), which requires the presence of relativistic electrons which would also produce synchrotron emission in the *NuSTAR* bandpass. Likewise, if the GeV emission is instead produced via hadronic emission mechanisms (that is,  $\pi^0$  decay) then we might not expect to observe a counterpart in the *NuSTAR* band, since the  $\pi^0$  emission is produced by ions with much lower energies than the synchrotron-emitting electrons observed by *NuSTAR*. This would be consistent with broadband spectroscopic analyses (e.g., Araya & Cui 2010; Saha et al. 2014), which suggests the need for both hadronic and leptonic emission mechanisms. It is also suggestive that the GeV centroid falls near enhanced emission observed at 24 and  $70 \mu$  (Hines et al. 2004) as well as near bright optical features in this region, both of which imply the presence of dense material and further supports a hadronic emission mechanism in that region. However, as the difference in the centroid regions is not strictly statistically significant (recall that all of the centroids are consistent the 90% level), we cannot make firm claims about separating the emission mechanisms without further improvements in the angular resolution of future GeV and TeV instruments. When those data are eventually available, combining the GeV/TeV data with these *NuSTAR* observations should prove fruitful.

#### 4.3. Curvature in the Continuum Spectrum

For the following discussion, we presume that the emission in the *NuSTAR* band is synchrotron radiation from electrons with 10–100 TeV energies, produced by diffusive shock acceleration.

The shape of the spectrum carries information about the source electron spectrum. For synchrotron emission (which is the only viable mechanism for the emission at the forward shock) from a power-law electron spectrum with an exponential cutoff, the resulting spectrum drops roughly as  $\exp(-\sqrt{\nu/\nu_{\text{rolloff}}})$ , where  $h\nu_{\text{rolloff}}$  is 1.9 times the photon energy at which electrons with  $E_m$  radiate the peak of their synchrotron spectrum (e.g., Pacholczyk 1969). However, more elaborate inhomogeneous models of shell SNRs can predict significantly different spectral shapes (e.g., Reynolds 1998). In the case of the XSPEC *srcut* model, the model produces a smooth

continuum over many decades in energy, from the radio to the X-ray band, with a characteristic frequency at which the spectrum gently rolls over. These frequencies are in the range  $10^{16}$ – $10^{18}$  Hz. This is sufficiently slow that over a relatively narrow bandpass in the hard X-rays the resulting spectrum can be reasonably fit by a power-law (i.e., 15–50 keV), though we do expect some steepening of the spectrum from the energy band previously sampled by *Chandra* to the *NuSTAR* band.

At the exterior of the remnant we find that the 15–50 keV power-law model underpredicts the emission at low energies and therefore does not explicitly require curvature in the spectrum. This is not surprising, as we expect there to be some “PSF bleed” of the central regions of the remnant that provides an additional soft ( $<10$  keV) component on top of the non-thermal continuum. However, in this region the non-thermal continuum spectrum as observed by *Chandra* is well-fit by a power-law spectrum with a substantially harder photon index (e.g.,  $\Gamma \sim -2.3$  for the northeast filaments from Patnaude & Fesen 2009). Given that the *Chandra* data are uncontaminated by neighboring thermal emission, we can then assume that the power-law index steepens from  $\Gamma \sim -2.3$  to  $\Gamma \sim -3.05$  from the 4–6 keV band to the 15–50 keV band, with no further curvature required by our data across the 15–50 keV band.

In the central emission regions the *NuSTAR* data alone demonstrate that the softer power-law fit in the 15–50 keV band overpredicts the 3–15 keV observed emission. We actually expect more contamination by thermal plasma(s) in the central extraction regions. This implies that, if anything, there is more curvature in the central knots than in the exterior filaments.

We can naively apply the *srcut* model to analyze the data to compare the *NuSTAR* 15–50 keV results to the 4–6 keV results from *Chandra*. The *srcut* model predicts a gradually steepening spectrum above  $h\nu_{\text{rolloff}}$ . We calculated a custom *srcut* model for the steep radio spectral index of Cas A,  $\alpha = -0.77$ , and calculated the slopes over frequency ranges of a factor of  $10^{0.5}$ , roughly the photon energy range from 15–50 keV. Then the measured values of  $\Gamma$  uniquely predict  $h\nu_{\text{rolloff}}$  for a simple single *srcut* component. We find that the central-knot value of  $\Gamma = -3.35$  requires  $h\nu_{\text{rolloff}} = 1.3$  keV, while the outer-filament value of  $\Gamma = -3.06$  requires  $h\nu_{\text{rolloff}} = 2.3$  keV. We can perform the same operation for the power-law fits in the range of 4.2–6 keV done with *Chandra* data (Patnaude et al. 2011)<sup>14</sup> from their 2011 data, they find  $\Gamma$  of  $-2.85$  and  $-2.56$  for a sample of exterior filaments and for a region similar to the *NuSTAR* central knots, respectively, implying  $h\nu_{\text{rolloff}}$  values of 0.44 and 1.1 keV. Thus, while our 15–50 keV power-law indices are steeper than their 4.2–6 keV values, they do not steepen as much as one would expect from a single power-law electron spectrum with an exponential cutoff.

We conclude that while softening of the spectrum is evident, it requires either electron distributions with a range of cutoff energies, as might naturally be expected from integrating over multiple shock regions, or a modification of shock acceleration physics that produces a more gradual cutoff in the electron distribution than exponential. Since one careful calculation of this cutoff (Zirakashvili & Aharonian 2007) yields a distribution which at the shock is actually exponential in the square of electron energy, i.e., a much steeper cutoff, this latter

<sup>14</sup> While they find a significant steepening between 2000 and 2011, the implied change between the 2011 fits and the epochs of the *NuSTAR* observations is considerably smaller than the errors and we shall ignore it.

possibility seems less likely. We infer that even over the spatially localized regions of the forward blast wave and of the central knots, conditions must vary sufficiently to provide a range of electron cutoff energies whose superposition gives us the very gradual steepening we observe. Future *NuSTAR* observations of the historical Type Ia SNRs may show if they share this property.

We do urge caution in using the  $h\nu_{\text{rolloff}}$  frequency reported above as a proxy for the maximum energy of the emitting electrons. Doing so requires some knowledge of the radio-spectral index (assumed to be 0.77 above), which is known to vary across the remnant (Anderson & Rudnick 1996) as well as spatially resolved knowledge of the radio 1 GHz flux. The latter measurement often suffers from a lack of dynamic range in Cas A (i.e., the northeast rim is undetected at radio wavelengths but bright in synchrotron X-rays). This introduces enough degeneracies in the `srcut` model fits that we do not include fits here with all of the parameters allowed to vary. However, the above analysis is entirely self-consistent and our result is relatively independent of the particular parameters used in `srcut`.

#### 4.4. Comparison with Spatially Integrated Measurements

No previous instrument could spatially resolve the different emission regions in Cas A above 10 keV. However, by considering the power-law spectral index integrated over the remnant it could be possible to confirm our finding that the softer inner region dominates the total flux. The integrated emission detected by previous hard X-ray non-imaging instruments (e.g., The et al. 1996; Allen et al. 1997; Vink et al. 2000; Renaud et al. 2006; Maeda et al. 2009) extends to high energy (>100 keV), so that, in principle, the spectral index could be well-constrained. Table 3 compiles the results of these previous measurements of the integrated spectrum of Cas A. It is clear different measurements disagree at levels greater than the formal statistical errors. This is likely due to systematics associated with the background-dominated measurements or the difference in energy bands in which the different instruments are sensitive. What is clear is that previous spatially-integrated measurements are not in agreement with one another and do not have statistical or systematic precision sufficient to confirm or rule out *NuSTAR*'s finding that the softer central emission dominates the integrated flux.

## 5. CONCLUSIONS

We have shown that the hard X-ray emission from Cas A up to 50 keV resolves into two main populations: fainter outer filaments and bright central knots which dominate the emission above 15 keV. These two populations show different unbroken power-law spectra over the 15–50 keV *NuSTAR* band, with the central bright knots having a significantly softer spectra than the dim outer rims. We view this as evidence for two distinct populations of electrons responsible for the exterior and central emission and therefore argue that the central knots are in fact located in the interior of the remnant rather than at the forward shock and seen in projection.

The origin of the population of energetic electrons in the interior of the remnant remains a mystery, especially as the morphology above 15 keV does not appear to follow that of any other waveband. Some of the bright central knots appear to be spatially coincident with regions known to show rapid

(~yearly) variability in both soft X-rays and the radio, which may evidence for active particle acceleration in the interior of Cas A or for significant changes in the physical environment in the center of the remnant. Future *NuSTAR* observations with a longer temporal baseline may be able to test for changes in the flux of particular regions above 15 keV.

The steepening of the non-thermal spectrum from the *Chandra* band to the *NuSTAR* band requires either an electron distribution that cuts off more gradually than an exponential. While this could be due to some modification in the shock acceleration physics, we instead conclude that conditions in the forward shock blast wave produce a range of cutoff energies in the electron spectrum even on small spatial scales.

We have shown that imaging in the *NuSTAR* band can be useful for interpreting results from the GeV/TeV energy bands. The association of the centroid of the TeV emission with a region bright in the *NuSTAR* band and the lack of any such association with the centroid of the GeV emission can be naturally explained by a leptonic emission mechanism for the former and a hadronic emission mechanism for the latter. The interpretation that there are both hadronic and leptonic emission mechanisms at work in Cas A is consistent with broad-band spectrum fitting and may bear out as the measurements in the GeV and TeV bands improve.

B.G. thanks Una Hwang for the *Chandra* 4–6 keV band image. This work was supported under NASA contract NNG08FD60C and made use of data from the *NuSTAR* mission, a project led by the California Institute of Technology, managed by the Jet Propulsion Laboratory, and funded by NASA. We thank the *NuSTAR* Operations, Software, and Calibration teams for support with the execution and analysis of these observations. This research has made use of the *NuSTAR* Data Analysis Software (NuSTARDAS), jointly developed by the ASI Science Data Center (ASDC, Italy) and the California Institute of Technology (USA).
